Keywords: Coronary perforation; Angiogram; Complications; Conal artery

Introduction

The major complication rate with coronary angiography is less than 1%. Coronary branch perforation is not so uncommon complication during percutaneous coronary intervention but it is very rare during diagnostic angiogram. Management depends on site of perforation or development of pericardial effusion and its effects on hemodynamic status. Management of coronary perforation incudes balloon occlusion of the vessel, use of a covered stent, distal fat or coil embolization and rarely emergency surgery. Cardiac tamponade and hemodynamic compromise needs pericardiocentesis. We present you a case of 32-year-old gentleman who had a coronary artery branch perforation during diagnostic coronary angiogram and it was managed conservatively.

Case report

A 32-year-old gentleman was admitted for evaluation of unstable angina. His complete blood count, renal and liver function tests, coagulogram were unremarkable and echocardiography showed normal ejection fraction with no regional wall motion abnormalities. He was planned for coronary angiogram. Right radial artery access was achieved and a 5 Fr Tiger (TerumoTM, Japan) catheter was used. Left coronary artery was essentially normal. The right coronary ostium was hooked, pressure waveform showed no dampening, ostial position was confirmed by a small test injection. However, during the actual contrast injection using manual injection, the catheter super selectively intubated the Conal branch of right coronary artery and 3 ml of dye was injected before stopping the injection. Following this, the distal tip of the Conal artery perforated leading to extravasation of dye into myocardium as shown in Figure 1. His vitals remained stable and a check angiography showed no further leak from the perforation site and confirmed the persistence of dye staining of the myocardium as shown in Figure 2. Post procedurally he was kept under observation for the next 48 hours and monitored for effusion. His vitals remained stable and no pericardial effusion developed and he was discharged after 3 days.
introduction of high pressure in relatively small and delicate vasculature and higher pressures may increase the risk of perforation lead to the use of manual syringe for coronary angiograms.

Coronary perforation following angiography is a very rare complication with only three cases reported in the literature till now. In two of the cases the right coronary artery branch was involved and in one case side branch of the left main coronary artery was involved [5,6]. In our case when a 5 Fr Tiger (TerumoTM, Japan) catheter was used to inject contrast into the right coronary artery, just before injecting the catheter tip accidentally intubated the branch of right coronary artery super selectively leading to the perforation of the tip of the branch, even though the position of the catheter was confirmed prior by a test injection. Perforation of the branch lead to accumulation of the dye in myocardium. An immediate echocardiogram showed no pericardial effusion. In our case the patient has not developed any hemodynamic compromise or effusion so he was kept under conservative management and followed up for development of any pericardial effusion. We conclude that conservative management can help in some cases of perforation during angiography provided the perforation was limited to myocardium and no effusion is noted. We also conclude that pressure tracings should always be monitored during angiography and dye injection to be stopped immediately when there is deep cannulation of the branches.

Conclusion

Coronary angiography is a relatively safe procedure in current generation. However, complications such as side branch perforation can occur. Pressure tracings should always be monitored during the procedure and dye injection should be stopped when there is deep cannulation of the branches. Conservative management will suffice in a hemodynamically stable patient if no effusion is seen.
